Introduction

In this project, we participate in a Kaggle competition where the goal is to design a machine learning algorithm to classify locations around the world on 2 different classes :

- Crop land : 1
- Non-crop land : 0

To do so we have a dataset that containing 12 months of meteorological and climatological data. This set is composed of a 216 features subset of the [CropHarvest](#) dataset where every data points corresponds to a geographical location.

The goal of this project is to implement and train classification algorithms in order to have the highest performance on the test set available on Kaggle. The scoring in this competition is based on the [f1 score](#).

Four baselines needs to be beaten on this competition :

1. A dummy classifier that predicts the most frequent class in the set : **0.71886**
2. A weak machine learning algorithm : **0.94736**
3. A stronger machine learning algorithm : **0.97841**
4. The TA's best baseline : **0.99516**

We will first see which algorithms and methodologies were done for this competition. Then we will see and discuss our results.

Methods

After checking on the 216 features, we checked for any redundancy and manage to manually **select 50 features**.

Feature preprocessing

To preprocess our dataset, we use [Power Transformer](#) to render data more Gaussian like. Even though we used a lot of tree based method (see the [Models Used](#) section), this preprocessing can help when using other models such as MLP.

Training Pipeline

We put our training in a pipeline with the [make_pipeline](#) module from Scikit-Learn. This helped us to train several models and stack them. To choose either the one with the best score, or to bag them in a Voting classifier.

Basic Pipeline

The basic pipeline trains and evaluates each model by using [cross_val_score](#), a function that returns all the score of the [Stratified K-fold](#) cross validation. By taking the mean for each fold after evaluating and stacking their score in an array, we can see which model is performing better in general. The default number of fold for our cross validation during basic training is 5. After using that, we re fit our model by using [SelectFromModel](#)

Hyper Parameter tuning

The hyperparameter tuning is done by using a cross validation grid search with [GridSearchCV](#). Our cross validation strategy is still [Stratified K-fold](#) with **10** folds.

Models used

- [Multi Layer Perceptron](#) : A "vanilla" feed forward artificial neural network classifier implemented with Scikit Learn library [MLP_Classifier](#). We tried this model to see if it can perform well on our big number of features.
- [Random Forest](#) : A model that fits a certain number of [decision tree classifiers](#) on sub-samples of the dataset and uses the averaging to improve accuracy of predictions and control over-fitting.
- [AdaBoost](#) : A meta-estimator that boost a classifier so that it can focus on most difficult cases. Our boosted model is a basic [Decision Tree classifier](#).
- [Voting](#) : An ensemble method that trains on a numerous set of models and predicts the output based on voting with majority of models with the highest probability. Here we used Voting on our 3 previous classes.

Results

Here we show the best hyper parameters and results we had for each models. Some other model were omitted from this report such as SVM and K-NN due to their poor results on Kaggle public test set. The Competition has 2 set score :

- A public set which is calculated with approximately 30% of the test data.
- The final results on the test set based on the other 70%.

| Model | Hyper Parameters | F-1 score (train set) | F-1 score (public set) | F-1 score (private set) |
|------------------------------------|---|-----------------------|------------------------|-------------------------|
| <i>MLP</i> | -Random state : 1 -Activation Function : tanh -Solver : " Adam " | 0.863767 | 0.63707 | |
| <i>Random Forest</i> (50 folds) | - n_estimator : 450 | 0.885561 | 1.0 | |
| <i>AdaBoost</i> | -n_estimators : 100 -learning rate : 0.01 | 0.848781 | 0.69721 | |
| <i>Voting</i> | NA | NA | 0.96470 | |

Discussion

After having those 3 results we were astonished by the drop with MLP and AdaBoost on the test set, but this is certainly due that both model cannot fit all the data (MLP fits). This is also why Random Forest works the best here, because it is an ensemble of numerous decisions trees. Even though we increase the number of fold way too much to have the best F-1 score possible.

After discussing the results with other students who used the same model, it also seemed that the feature selection also has its importance on the results of our Random Forest, where some of them didn't manage to entirely have 100% accuracy on the public set.

Statement of Contribution

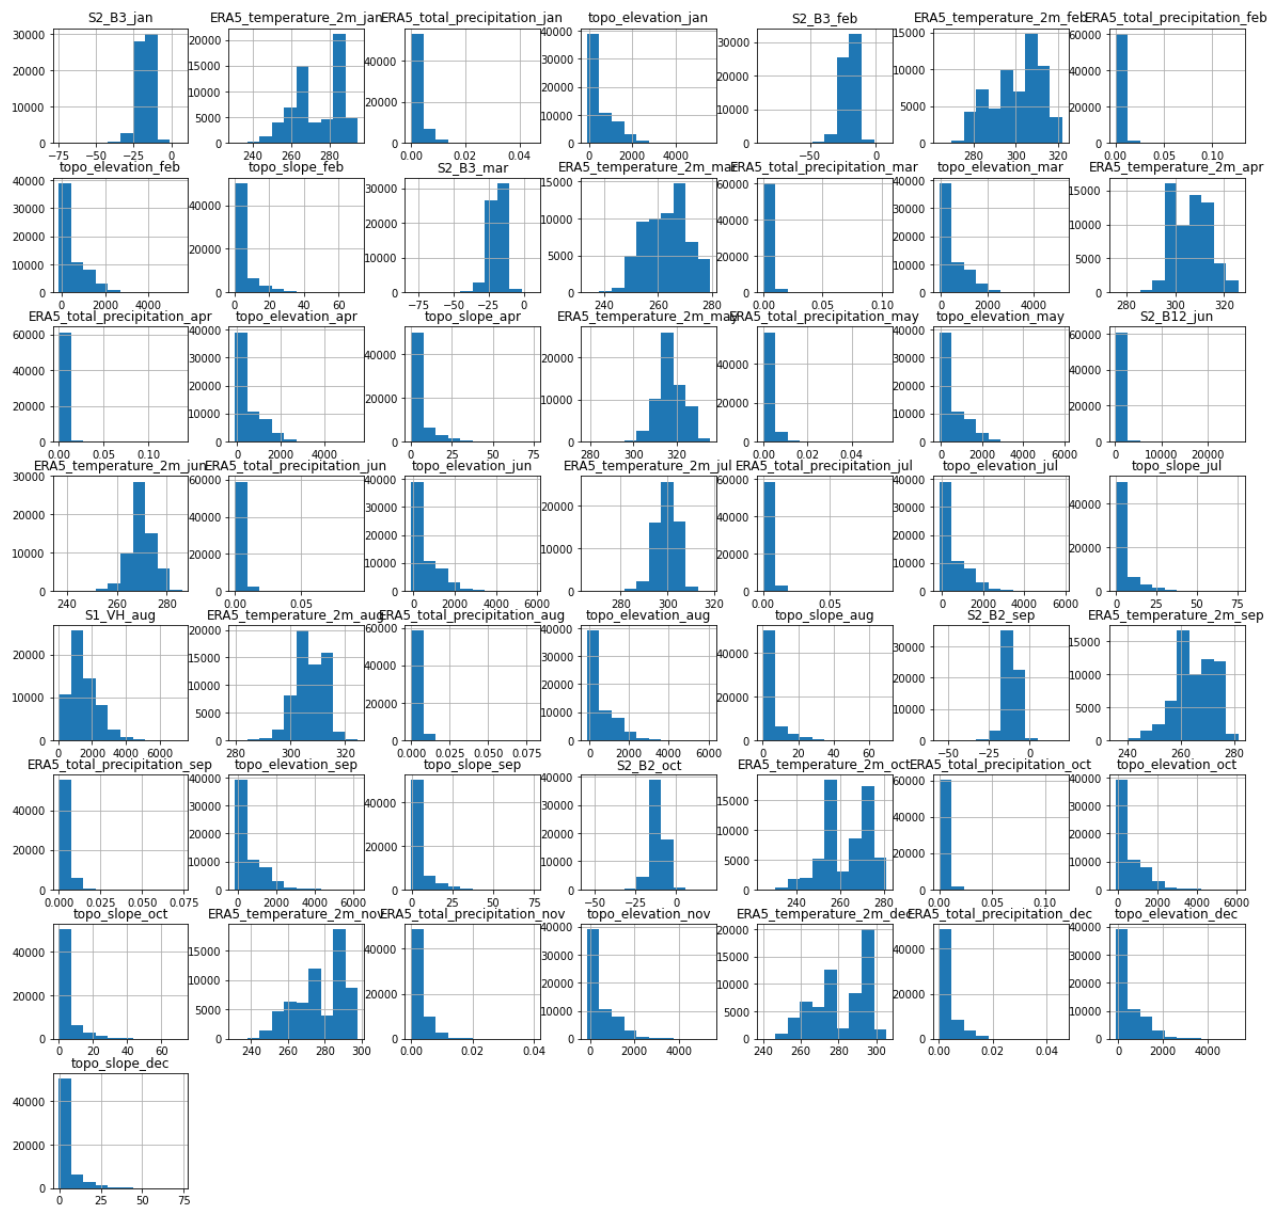

We hereby state that all the work presented in this report is that of the authors
